Advisor: Richard Carbone

Accepted: March 19, 2015

Abstract

Malware functionalities have been evolving and so are their target platforms and architectures. Non-PC appliances of different architectures have not traditionally been frequent targets of malware. However, many of those appliances, due to their enhanced processing power and/or low maintenance, provide ideal targets for malware. Moreover, due to the lack of security for home routers, they often remain infected until replaced, thereby providing longer persistence for a malware. Recently, there has been a surge in malware for the MIPS and ARM architectures, targeting specific routers, DVRs, and other appliances. These network devices, in comparison, get less focus from vulnerability researchers and firmware patch application by end-users. This increases the risk of compromise and requires additional skills to cope with malware exploiting these platforms. This paper discusses various tools and techniques for reversing malware for the MIPS platform. We perform static and dynamic analysis of a MIPS malware, discuss its Command & Control mechanism, and provide detection of its network communication.
Acknowledgements

I would like to thank my advisor Richard Carbone for his valuable feedback and guidelines on this paper. Moreover, I also thank my employer TELUS Security Labs (telussecuritylabs.com) for providing me the tools and environment to perform research for this paper.

M. J. Bohio, mjbohio@gmail.com
1. Introduction

MIPS (Multiprocessor without Interlocked Pipeline Stages) architecture is a Reduced Instruction Set Computing (RISC) technology that is widely used in embedded devices. As per the statistics mentioned in MIPS instruction set (n.d.) and MIPS architecture (n.d.), MIPS-based processors are routinely used in routers from Cisco, Linksys, Mikrotik, Cable/DSL modems, video gaming consoles from Sony and Nintendo, printers, set-top boxes, and more. The ARM (Advanced RISC Machines) architecture is the most widely used architecture in smart phones, TVs, set-top boxes, and mobile devices.

Malware produced for network devices have been far less in number compared to those produced for PCs. However, this number is growing. According to various sources (Infodox, 2011; Janus, 2011) the earliest known malware-targeting MIPS platform is Hydra – an open source botnet framework released in 2008. It was designed for extensibility and features both a spreading mechanism and DDoS functionality. In 2009, another malware, Psyb0t, was found in-the-wild targeting routers and high-speed modems. Its botnet, with an estimated 100,000 compromised devices, was then used in a DDoS attack against DroneBL, an IP blacklisting service (Psyb0t, 2013).

In 2010, an IRC bot named Chuck Norris was found infecting routers and DSL modems. In addition to spreading by brute forcing routers’ passwords, this malware also exploited an authentication bypass vulnerability in D-Link routers (McMillan, 2010). Another IRC bot named Tsunami supported various commands and modified the DNS server setting in the configuration of the infected devices (Janus, 2011). This trend has been observed in more recent malware as well and is effective in redirecting traffic to malicious servers controlled by attackers.

In 2012, another IRC bot named LightAidra was found. It supported several architectures including MIPS, MIPSEL, ARM, PPC, and SuperH (Fitsec, 2012). It exploited a D-Link router vulnerability and modified firewall settings using iptables. The source code of LightAidra is freely available on the Internet as an open source project. In 2013,
Symantec discovered a worm called *Darlloz* (Hayashi, 2013). This malware spread by exploiting a PHP vulnerability identified by CVE-2012-1823. It targeted various architectures including x86, ARM, MIPS, and PowerPC, thereby termed as an Internet of Things (IoT) Worm by Symantec (Hayashi, 2014). In order to block users from connecting to the infected device using Telnet, it drops Telnet traffic via *iptables* configuration and terminates the *telnetd* process. According to an investigation by Symantec (Hayashi, 2014), *Darlloz* compromised more than 31,000 devices by February 2014. Its newer variants supported mining of cryptocurrencies (Mincoins and Dogecoins) and exploited a default password on Hikvision DVR cameras (Ullrich, 2014b). An interesting aspect of the *Darlloz* worm is that it specifically targets rival worm *LightAidra*. *LightAidra* stores its process ID in various files including `/var/run/.lightpid`, `/var/run/.aidrapid`, and `/var/run/lightpid`. The *Darlloz* worm attempts to terminate the processes whose PIDs are stored in these files and deletes *LightAidra* files from the infected device (Blinka, 2014).

In February 2014, Dr. Johannes Ullrich of the SANS Technology Institute discovered a new worm called *TheMoon* (Ullrich, 2014a). This malware was specifically targeting Linksys routers. One known instance of this malware, MD5:A85E4A90A7B303155477EE1697995A43, can target the following specific router models: E4200, E3200, E2500, E300, WRT610N, E1000, E1200, E1500, E1550, E2000, and E3000 (Constantin, 2014). The malware exploits a command execution vulnerability when parsing the ‘*ttcp_ip*’ parameter value sent in a POST request. It downloads a copy of itself by running the *wget* command on the vulnerable router after exploiting the vulnerability. The malware was named after the Hollywood movie, ‘Moon,’ because it contains several strings such as Moon, Gerty, Lunar, Sam, and Jupiter that match various characters in the movie. These characters in the code perform various tasks such as analysis of the infected device, harvesting targets and sending fingerprinting/exploit requests, and keeping logs. In the same year, malware *Elknot* was found targeting x86, ARM, and MIPS platforms (Kernelmode.info Forum, 2013), whereas *GoARM/Ramgo* targeted the ARM architecture (Adrian, 2014b). Moreover, newer versions of the *BlackEnergy* Backdoor (that has been used in APT attacks in the past) have been found...
using plugins that target both the ARM and MIPS platforms (Baumgartner & Garnaeva, 2014).

Around mid-2014, a Backdoor/DDoS malware that is known by different names including Spike, AES, and Dofloo DDoS malware was discovered. Samples of this malware have been found targeting 32-bit and 64-bit Linux and Windows platforms as well as MIPS and ARM architectures. A toolkit that generates samples of the Spike DDoS malware was analyzed by the Akamai PLXsert Team (Akamai, 2014), and its report states that several Akamai customers have been targeted by DDoS attacks launched from this botnet. The peak attack by the Spike DDoS botnet, according to Akamai, was 215 Gigabits per second (Gbps) and 150 million packets per second (Mpps) (Akamai, 2014). This malware has also been discussed on the Kernelmode.info forum (Adrian, 2014a). In this paper, we analyze a sample of the Spike DDoS malware for the MIPS architecture and examine its commands, communication, and other operations.

2. Debugging Environment Setup

In order to analyze the malware binary for the MIPS architecture, the following tools were used:

- Oracle VM VirtualBox 4.3.7 r91406
- Ubuntu 12.04.4 LTS
- OpenWrt- Barrier Breaker (Bleeding Edge, r39584)
- Qemu 1.6.2
- IDA Pro 6.5.140116 (32-bit)
- Wireshark 1.10.5
- 010 Editor 3.0.4
- Python 2.7

After installing Ubuntu Linux on the Oracle VM VirtualBox, the OpenWrt Linux distribution was compiled and installed on the VM. OpenWrt also created the cross-
compiler toolchain that is required to run MIPS binaries. The firmware for Atheros AR71xx routers was selected with the OpenWrt installation.

After installing OpenWrt, Quick Emulator (QEMU) was installed in order to provide hardware virtualization for OpenWrt and to run MIPS binaries in the OpenWrt environment. The detailed guidelines for these installations are not in the scope of this paper but can be found in other resources (Craig, 2011; Võsandi, 2013). The QEMU installation created binaries for both Little Endian (`qemu-mipsel`) and Big Endian (`qemu-mips`) modes. Since the malware sample under analysis is compiled in Little Endian format, `qemu-mipsel` was used to run it. This will be demonstrated in the next section.

The malware was run in both a controlled environment (Host-only Adapter) as well as with Internet access using the Bridged Adapter. The non-controlled environment was provided in order to capture live traffic from a control server.

### 3. Analysis of the Malware

The sample under analysis is a 32-bit Little Endian ELF binary for the MIPS architecture, also known as Backdoor Spike DDoS or Dofloo. This binary was statically compiled and left unstripped; as such it contains all of its strings and import function names. The binary’s MD5 hash is `99ccdc5772a827917ae6cc8e29c78aee`. These attributes are shown in the following figure:

![Figure 1: md5sum and file attributes of the sample.](image-url)
The analysis of this malware includes both its behavioral and technical analysis which will be described in this paper.

3.1 Behavioral Analysis

When the malware was first run in a restricted environment (host-only network) it did not perform any network communication. Upon providing it access to the Internet, the malware contacted its Command & Control (C2) server at IP address 60.169.80.91, port 48080/TCP. The malware sent out some system information and received some responses. It continued exchanging messages with its control server. Other than communicating with the control server, no other suspicious connections by the malware, such as any DDoS operations, were observed in the traffic. This will later be clarified when the server responses are parsed and interpreted in the following subsections.

3.2 Technical Analysis

On the Ubuntu VM where OpenWrt and QEMU were installed, the sample file name “99ccdc-spike” was run as shown in Figure 2:

![Figure 2: Sample run and waiting for the gdb connection.](image)

Among the above parameters, the “-E” parameter specifies the IP address of the system from which the IDA debugger will be attached to the malware process. The “-g” parameter with value “1234” puts the malware execution on hold until a debugger is attached to it on port 1234/TCP. On the remote system with IP address ‘192.168.56.1,’ the IDA debugger was configured to connect to the Ubuntu VM having IP address ‘192.168.56.101’ on port 1234. Once the attachment to the malware process was successful, the debugging session began.

M. J. Bohio, mjbohio@gmail.com
In this section, functions related to C2 operations, communication mechanisms, and malware persistence will be discussed. The important code instructions have been explained using comments on their right side; however, further information on MIPS instructions can be found in Frenzel (1998) and MIPS instruction set (n.d.).

When the malware is started, it checks if its command-line has any arguments. If none are found then it assumes it is running for the first time on the target system. It then calls function \_Z8autobootPc, which attempts to run the following commands in order to set up system persistence (reboot survival):

```
    sed -i -e '/exit/d' /etc/rc.local
    sed -i -e '/^r\n|r\n$'/d' /etc/rc.local
    sed -i -e '2 i%s/%s'
    /etc/rc.local
```

The main function of this malware calls function ‘\_Z14_ConnectServerv’ which connects to one of the C2 servers with IP address 60.169.80.91 and port 48080/TCP. The information concerning this control server is stored in global variable ‘m_OnlineInfo’ using a simple obfuscated format. The malware adds a constant value of 0x4E20 (20000) to compute the actual aforementioned IP address and port. The following code/data snippets in Figures 3 and 4 demonstrate this behavior:

```
004CF964 .globl m_OnlineInfo
004CF964 m_OnlineInfo:.byte 0xFE   # |     # DATA XREF: ServerConnectCli(void)+BCTo
004CF964 m_OnlineInfo:.byte 0x77   # v     # ServerConnectCli(void)+ECTo
004CF965 .byte 0x77   # v
004CF966 .byte 0xFE   # 
004CF967 .byte 0x77   # v
004CF968 dword_4CF968:.word 0x5850581C   # DATA XREF: ServerConnectCli(void)+F4Tr
004CF96C dword_4CF96C:.word 0x6DB0   # DATA XREF: ServerConnectCli(void)+G4Tr
004CF970 .globl encode_url     0x6DB0 +0x4E20 =0xBBD0 (Port 48080)
```

Figure3:m_OnlineInfo data structure.
If the malware cannot connect to the aforementioned control server, it may try connecting to another server with IP address 183.60.149.199 on the same port. However, it does not perform any obfuscation of this secondary control server’s IP address. This will be demonstrated while discussing one of the program threads (pthreads) started by the malware.

In function main, the malware sets some signals and creates the program threads as shown in Figure 5:

Figure 5: pthreads called in main function.
The functionalities of the above threads are described in the following subsections.

3.2.1 ‘SendInfo’ thread

This thread is implemented in function “_Z8SendInfoPv”. It attempts to calculate the network/CPU speeds and periodically updates the control server about this information. This information is believed to be used by attackers to evaluate the operational capabilities of their bots and thus will assign DDoS tasks according to their CPU power and network bandwidth/speed.

This function also checks ifconfig information for Ethernet interfaces ranging from ‘eth0’ through ‘eth9’. It reads data from pseudo-file /proc/net/dev and computes network speed in Mbps. This file provides statistics on each network interface regarding the number of bytes sent/received, number of inbound/outbound packets, and more. Please refer to Figures 6, 7, and 8 which depict the code where this information is collected:

Figure 6: Construct interface ‘ethN’ and call my_ipconfig.

M. J. Bohio, mjbohio@gmail.com
The malware also calculates the percentage of CPU usage by reading and processing
values in /proc/stat. This pseudo-file keeps various statistics about the system since it was
last run. The following figure shows two calls to a function that reads /proc/stat:

```
0040939C addiu $v0, $fp, 0x738+var_178
004093A0 move $a0, $v0
004093A4 jal _Z10get_occupyP6occupy # get_occupy(occupy *)
004093A8 nop
004093AC li $a0, 1
004093B0 jal sleep
004093B4 nop
004093B8 addiu $v0, $fp, 0x738+var_2E0
004093BC move $a0, $v0
004093C0 jal _Z10get_occupyP6occupy # get_occupy(occupy *)
004093C4 nop
004093C8 sw $zero, 0x738+var_70C($fp)
004093CC j loc_409420
004093D0 nop
```

Figure 9: Two function calls for reading /proc/stat.
Next, Figure 10 shows a part of the code inside function \( \_Z10get\_occupyP6occupy \):

```assembly
004065A0  addiu $sp, -0x438  
004065A4  sw $ra, 0x438+var_4($sp)  
004065A8  sw $fp, 0x438+var_8($sp)  
004065AC  move $fp, $sp  
004065B0  sw $a0, 0x438+arg_0($fp)  
004065B4  lui $v0, 0x4A  
004065B8  addiu $a0, $v0, (aProcStat - 0x4A0000) // "/proc/stat"  
004065BC  lui $v0, 0x4A  
004065C0  addiu $a1, $v0, (aR - 0x4A0000) // "r"  
004065C4  jal open  // Open file  
004065C8  nop   
```

Figure 10: Read /proc/stat.

The malware then prints the CPU usage percentage and network speed information into a pre-defined format. If the socket has been created, it sends out that data to its control server. Figure 11 demonstrates this behavior:

```assembly
00406944  loc_409588:  // v0 = 0x3F800000  
00406944  lw $v0, _cpu_used  
00406948  lw $t1, 0x78+var_6E  // [aR] = [0x407FF000] - 0  
0040694C  addiu $a0, $v0, 0x78+var_78  // [aR] = [0x407FF000] - "50.87 Mbps"  
00406950  sw $a0, 0x738+var_728($sp)  
00406954  la $a1, INFO_OFF  // "INFO: %0.2f\%s"  
00406958  move $a2, $v0  // a2 = 0  
0040695C  move $a3, $v1  // a3 = 0x3FF00000  
00406960  jal printf  // prints "INFO:1%50.87 Mbps"  
00406964  nop  
00406968  lw $v0, MainSocketA  // Check if socket has been created?  
00406970  beqz $v0, loc_409588  
00406974  nop   
```

Figure 11: Print INFO data and send to the server.
The periodic speed information sent by this thread to its control server is shown in Figure 12 that represents the traffic captured through Wireshark:

3.2.2 'backdoorA' Thread

This thread collects system information and sends it out to the control server. The information sent out by this thread includes OS Kernel version, CPU speed, total memory size, used memory size, and some hard-coded strings such as ‘VERSONEX’ and ‘Hacker.’ These strings have been observed in several samples of this malware family. The following figure shows the initial request captured through Wireshark:

Figure 12: INFO packets sent by the malware.
Figure 13: backdoorA thread identifying to the server with system information.

This thread contains information about a secondary control server that could be contacted in case the primary control server is not available. The following figure shows the code containing IP and port number of the secondary control server:

```
00400B20  li $a0, 0xBBDD0       # Port = 0xBBDD (48080)
00400B24  jal ntohs
00400B28  nop

004099D8 nve $a3, $zero                # Send
004099DC jal send
```

Figure 15: Print and send system information.

In response to the above request, the server sent the following command/data that is captured and parsed by Wireshark:

```
```

M. J. Bohio, mjbohio@gmail.com
In the above response, the first DWORD '07 00 00 00' is the command code. The payload size of the server response is 0x19D; however, the malware parses only the fixed size 0x19C (412) bytes of it. The command codes expected by this thread are 5, 6, and 7. The following code snippet demonstrates how the server response is received and parsed:
Thus, the commands supported by this thread are:

- **CmdShell** (0x05)
- **DealwithDDoS** (0x06)
- **Kill a process OR continue** (0x07)
Each of the above commands and its functionality are described in the following subsections.

3.2.2.1 CmdShell (0x05) Command

If the command code matches 0x05, the malware copies data after the first DWORD in the server response to a buffer. It then calls function “_Z8CmdshellP8_MSGHEAD”, which then calls the ‘System’ function to execute a command. The malware locates the shell command at offset 0x100 (256) within the data part of the server response. The command string has to be Null-terminated, whereas the rest of the data in the server response was redundant and not used while executing command 0x05. The following code snippets demonstrate this behavior:

```
00406fc4 loc_406fc4:  # CODE XREF: _ConnectServerA(void)+A9C1f
00406fd4 addiu $a0, $fp, 0x1060+var_c10

004072c move $a0, $v0
004072c jal system # Execute the command
004073c nop .
```

Figure 19: Inside Cmdshell runs command at offset 0x100.

Since the control server did not send command 0x05 at the time of this research, a Python script (see Appendix A for details) was written by the author that listened for a message from the malware and sent the command 0x05. For this purpose, the response containing
command 0x07, which was received earlier from the actual control server, was modified to command code 0x05 and a shell command at offset 0x100 (starting from the command data part) was sent to the malware. As a result of sending that command, the malware created a text file with the string that is written to it via the ‘echo’ shell command. The following figure demonstrates the shell command that was sent to the malware using the Python script:

![Figure 20: Modified response sent with Shell command.](image)

**3.2.2.2 DealwithDDoS (0x06) Command**

When command code 0x06 is found, the malware performs AES decryption of the data that is sent in the server response. It then performs expansion of the decryption key and then calls function ‘\_ZN3AES9InvCipherEPh’ or ‘AES::InvCipher(uchar *)’ in a loop. In each round, 16 bytes of data is decrypted. Once decryption is completed, the malware calls function ‘DealwithDDoS(_MSGHEAD *)’. The following code snippets are used in these operations:

```
M. J. Bohio, mjbohio@gmail.com
```
Based on the static code analysis, when the ‘DealwithDDoS’ function is started, it calls various flooding pthreads depending on the instructions received from the control server. Since at the time of this research the control server did not send DDoS command 0x06, the complete structure of this command is not known. The flooding attacks supported by this function are found in the following pthreads:

- TCP_Flood
- CC_Flood
- CC2_Flood
- CC3_Flood

The following code snippets show some of the pthreads started by the DDoS function:

```assembly
    00409C70 loc_409C70:  # CODE XREF: _ConnectServerA(void)+44A9j
    00409C70 lui $v0, 0x4d
    00409C74 li $v1, 2
    00409C78 sw $v1, numer
    00409C7C addiu $v0, $fp, 0x1068+var_C10  # Pointer to server data after command code
    00409C80 move $a0, $v0
    00409C84 lui $v0, 0x4d
    00409C88 addiu $a1, $v0, (key_0 - 0x4D00000)
    00409C8C jal _2H5AESG32EPH  # AES::AES(uchar *) << AES KeyExpansion/initialization
    00409C98 nop ...
```

Figure 21: AES key expansion/initialization.

```assembly
    00409D2C move $a0, $v1 ...
    00409D30 move $a1, $v0
    00409D34 jal _2M5AES9InvCipherEPH  # AES::InvCipher(uchar *) << decrypts 16 bytes in each round...
    00409D3C lw $v0, 0x1068+var_1038($fp)
    00409D40 addiu $v0, 1
    00409D44 sw $v0, 0x1068+var_1038($fp)
    00409D48...
```

Figure 22: Decrypt DDoS command and call DealwithDDoS.

M. J. Bohio, mjbohio@gmail.com
Based on the static code analysis, in the case of CC_Flood (Figure 24) DDoS, the malware sends out HTTP GET requests until the ‘StopFlag’ is set to 1. The following are some of the headers used in building such requests:

M. J. Bohio, mjbohio@gmail.com
The **CC2_Flood** (Figure 25) and **CC3_Flood** (Figure 26) DDoS also send out HTTP GET requests with some minor differences. For example, headers used with CC2_Flood requests are as follows:

**Accept-Language**: zh-CN

**User-Agent**: Mozilla/5.0 (compatible; MSIE 10.0; Windows NT 6.1; WOW64; Trident/6.0)

**Accept**: text/html, application/xhtml+xml, */*

3.2.2.3 Kill a Process or Continue (0x07) Command:

This command checks if the value of its ‘pid’ global variable is non-Null; then it attempts to terminate the process with that process ID. If the value is Null, the malware continues to the beginning of the loop and sends the next request to the server. Notice that the functionality of this command does not require a large amount of data (0x19C bytes) to be sent by the server. However, since the length of the received data is hard-coded in several places, the control server appears to be sending garbage data along with command 0x07. The following code snippet demonstrates the functionality of this command:

M. J. Bohio, mjbohio@gmail.com
3.2.3 'backdoorM' Thread

This thread performs very similar functions to the ‘BackdoorA’ thread with the exception that it has one additional command 0x01. This command updates flag value ‘statM’ to zero. This flag found at the beginning of the function is used to determine whether to sleep for a certain amount of time or continue operations if it is zero. This is shown in the following figure:
3.2.4 Detection and Indicators of Compromise (IoC)

3.2.4.1 Traffic Detection

As described earlier, the first request sent out by the malware with system information has a fixed payload size of 0x400 (1024) bytes. This value can be checked as a ‘dsize’ value along with other patterns in a Snort signature. The following is a Snort signature that can be used to detect a malware request sent to its control server:

```
alert tcp $HOME_NET any -> $EXTERNAL_NET any (msg:"SpikeDDoS Malware Detection"; dsize:1024; content:"VERSONEX\3a\"; nocase; offset:0; depth:9; content:"MHz\7c\"; nocase; distance:4; within:48; content:"MB\7C\"; nocase; distance:3; within:8; content:"\00 00 00 00 00 00\"; distance:32; within:32; classtype:Botnet; sid:1100110010; rev:1;)
```

The server response sent to the malware must also be at least 0x19C (412) bytes. The first 4 bytes are command codes including 1, 5, 6, and 7. A signature for the server response is also possible but since the malware request has several options for pattern detection, it is sufficient for traffic detection and would be more efficient compared to signature detection for the server response.

3.2.4.2 Indicators of Compromise (IoC)

When the malware is started, it checks the number of its command-line parameters. If it does not have any parameters, it calls function ‘_Z8autobootPc’. In this function the malware sets up its reboot survival mechanism. It attempts to add itself to the following files:

- /etc/rc.local
- /etc/rc.d/rc.local
- /etc/init.d/boot.local

In the case of /etc/rc.local, the malware removes any lines containing string “exit”. As a result of this, a line containing string “exit 0” was deleted from the /etc/rc.local file on the infected system. Furthermore, the malware also removes any empty lines from this...
file. Commands that perform these operations were previously examined. The malware then adds itself with parameter “reboot” to file /etc/rc.local as shown in the following:

```bash
#!/bin/sh -e
/home/username/openwrt/staging_dir/target-mips_34kc_uClibc-0.9.33.2/root-ar71xx/MalwareFileName reboot
#
# rc.local
# [...truncated...]
```

In the case of /etc/rc.d/rc.local and /etc/init.d/boot.local an error occurred when passing a parameter pointer to the malware filename string. However, when the parameter was passed correctly by modifying register ‘a3’ value after instruction at address 0x0040AF40, the malware created the following entry in /etc/rc.d/rc.local with parameter “start”. It uses the same format string for adding itself to /etc/init.d/boot.local as well, as shown below.

```
/home/username/openwrt/staging_dir/target-mips_34kc_uClibc-0.9.33.2/root-ar71xx/MalwareFileName reboot start
```

Please note that these target configuration files may not exist on all systems. The malware does not check for the existence of these files before attempting to write its command-line to them.

### 4. Debugging Challenges and Workarounds

The malware sample under analysis frequently uses forks and pthreads. As a result, multiple threads and instances of the malware are instantiated. In order to analyze such a code flow, `gdb` debugger provides various custom options such as setting `follow-fork-mode` and `non-stop` mode. However, through IDA Pro debugger these custom options for remote `gdb` debugging could not be enabled. As a workaround, a `fork` call in the `main` function was deactivated with NOP instructions. Figures 28 and 29 demonstrate the code

M. J. Bohio, mjbohio@gmail.com
where the fork was disabled in order to continue debugging the subsequent operations of the malware:

![Original code with fork call.](image1)

![Disabled fork call.](image2)

After bypassing the fork call and some flag checks, when the first ‘pthread’ call reached the ‘SendInfo’ function, the debugging session with IDA debugger was terminated. Since IDA Pro was configured to use gdb debugger for remote debugging of the MIPS binary, the default operation of gdb is the ‘stop-all’ (all threads stopped) mode. Whereas for debugging asynchronous multi-threaded code, it requires operating in the ‘non-stop’ mode to allow threads other than the debugged thread to continue running. With very limited command line options supported via IDA Pro Command-line for gdb, it could not be determined whether any other method could be used to enable these custom options for use of the gdb debugger via IDA Pro. To address this issue, it was attempted to use gdb directly and to configure it to operate in the non-stop mode. As such, an instance of gdb compiled for the MIPS architecture was used to attach to the malware sample running within QEMU. However, when gdb with the non-stop mode attempted to attach to the remote process, it presented the following error message stating that the remote
process does not support the non-stop mode. Thus, this attempt was not successful either.

Figure 31 depicts this error message:

```
This GDB was configured as "--host=i686-linux-gnu --target=mips-openwrt-linux-elf-hs".
For bug reporting instructions, please see:<http://bugs.launchpad.net/gdb-linaro/>.
(gdb) show architecture
The target architecture is set automatically (currently mips)
(gdb) set pagination off
(gdb) set target-async on
(gdb) set non-stop on
Remote debugging using 192.168.56.101:1234
Non-stop mode requested, but remote does not support non-stop
```

Figure 31: Non-stop mode attempt via MIPS gdb.

Thus, for the debugging of threads, the binary was patched and pthread calls were replaced with direct function calls to thread functions. The following figure shows the modified calls to the thread functions:

```
00403FC    li     $a0, 1
0040400    jal    close
0040404    nop
0040408    li     $a0, 2
004040C    jal    close
0040410    nop
0040414    jal    _Z8SendInfoPu    # SendInfo(void *)
0040418    nop
004041C    loc_4041C:    # CODE XREF: SendInfo(void *)+1C↑j
004044C    jal    _Z9backdoorAPu    # backdoorA(void *)
0040442    nop
0040442    _Z9backdoorMPu    # backdoorM(void *)
0040448    nop
004044C    _Z9backdoorMPu    # backdoorM(void *)
0040450    nop
0040454    nop
004045C    nop
0040460    nop
0040464    nop
```

Figure 32: Modified calls to thread functions.

When each of the pthread functions was analyzed, it was found that they ran asynchronously in their respective infinite loops. However, certain information such as socket creation and the ability to start/stop certain operations are communicated through global flag variables. When asynchronous thread functions were executed in ‘all-stop’
Analysis of a MIPS Malware

M. J. Bohio, mjbohio@gmail.com

mode, it required the modification of certain jump instructions in order to debug the subsequent function.

As described in MIPS instruction set (n.d.) and various other documentations, the J-type or Jump instructions on the 32-bit MIPS architecture are comprised of 6-bit Opcode/Instructions and 26-bit jump target addresses. Since a 32-bit address value can only be represented within 26-bits of a jump instruction, the address is divided by 4 before using it with a jump instruction. In order to modify a jump value to be used in a MIPS instruction, the following formula is used:

\[ \text{Operand Address (26-bits)} = \frac{(\text{target destination address})}{4} = \text{quotient} \& 0x03FFFFFF \]

The ‘Operand Address’ of the jump target address is then prepended to the instruction opcode. The prepending is done in the Little Endian format due to the fact that the binary being analyzed is in Little Endian format. For example, the modified function call for pthread function ‘_Z8SendInfoPv’ in the aforementioned code is set to, in hexadecimal, ‘DF 25 10 0C’. The actual address of the ‘_Z8SendInfoPv’ function is 0x0040977C which is shown in the following code snippet:

```
0040977C: 0x0040977C  # SendInfo(void *)
0040977C: _Z8SendInfoPv:
0040977C:  \# CODE XREF: _ConnectServerA(void)
0040977C: \# main+150\p
0040977C:  var_6 = -6
0040977C:  var_n = -4
0040977C:  arg_0 = 0
0040977C:  addiu sp, -0x20
00409790:  sw ra, 0x20+var_n(sp)
```

Figure 33: Start address of ‘_Z8SendInfoPv’ function

Hence, the Operand Address with the ‘jal’ command is calculated as:

\[ \text{Operand Address} = \frac{0x0040977C}{4} = 0x1025DF \& 0x03FFFFFF = 0x1025DF \]
Thus, prepending the above value (0x1025DF) to the ‘jal’ instruction code (‘0x0C’) as in ‘DF 25 10 0C’ results in a call to the target function at the given address and is resolved by IDA Pro as “jal _Z8SendInfoPv” that is shown in Figure 32 above. By modifying the pthread calls, the thread functions can be analyzed without causing termination of the debugging session.

4.1 Jump to Self

When debugging malware on the x86 platform, a commonly useful instruction is ‘Jump to Self’ or 0xEBFE. This instruction is typically used when a researcher wants to pause code execution at a certain point while the debugger is not attached to it -- for example, in the case of code injection into a suspended process. With various tests it has been determined that on the 32-bit Little Endian MIPS platform, a jump instruction can be modified to ‘FF FF 00 10’ that causes it to branch-to-self.

5. Conclusion

In this paper, we have discussed debugging and code analysis of a Backdoor/DDoS malware sample for the MIPS architecture. The Spike DDoS malware supports various DDoS functions as well as allows the execution of Shell commands. In our research, we have observed that a majority of the malware for the MIPS platform, including a known APT malware, focus on DDoS functionality. Moreover, backdoor access, modification of DNS settings, and other spying mechanisms have also been used by some of these malware. These functionalities can be effectively leveraged by cyber criminals as well as nation-state actors to achieve their various agendas.

The current state of security for the majority of home routers lacks the fundamental mechanisms of scanning and eradicating malicious programs. Moreover, the awareness among end-users regarding the possible malicious usage of their network devices is minimal. As such, an infected home router often remains infected until replaced. This requires that Anti-Virus products, in addition to PCs and laptops, protect other home network devices as well. Both network device vendors and AV vendors need to provide

M. J. Bohio, mjbohio@gmail.com
mechanisms for auto-updating their devices’ firmware and eradicating malicious programs from them as well. This could perhaps help in minimizing these agents of DDoS and other malicious activities.

Appendix A

The following script was used to listen for the malware’s message containing system information. It then sends a shell command to execute on the infected system. The malware traffic was redirected by modifying the IP address of the secondary control server that is shown in Figure 14.

```python
import socket, re, sys, thread

def sendCmd(botconn, botaddr, shellcmd):
    data = botconn.recv(1024)
    if re.search("VERSONEX", data):
        botconn.sendall(shellcmd)
    botconn.close()

if __name__ == "__main__":

    HOST="
    PORT=48080
    s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
    try:
        s.bind((HOST, PORT))
    except:
        print "Bind failed!"
        sys.exit()
    s.listen(2)

    shellcmd = 
        "\x05\x00\x00\x00\x72\xf8\xf6\x64\x86\x68\x98\x16\xd4\xa4\x5e\xcc" + \
        "\x60\xea\x6d\x01\x01\x00\x00\x00\x25\x9e\x95\x7c\xb0\x92\xd0\x00" + \
